Consumption Adjustment under Changing Income Uncertainty

by Joon-Ho Hahm and Douglas G. Steigerwald
University of California at Santa Barbara

July 11, 1997

Abstract

We study the role of income uncertainty in an intertemporal optimization model of consumption that includes precautionary saving. In contrast to previous studies, we focus on time-series variation in income uncertainty. Our time-series measure of income uncertainty is constructed from a panel data set of economic survey forecasts. We find evidence of precautionary saving in that increases in our measure of income uncertainty are related to increases in aggregate rates of saving and growth rates of aggregate consumption. We also find evidence that anticipated income growth rates have much less explanatory power for consumption growth rates after conditioning on income uncertainty. The overall evidence indicates the presence of forward-looking consumers who gradually adjust precautionary savings in response to changing income uncertainty.

(JEL E21, D91)
1. Introduction

The permanent income hypothesis (PIH) states that individuals base their consumption on the annuity value of current financial and human wealth.\(^1\) Hall (1978) proposed a simple statistical test of the PIH that has spawned a large literature. Although Hall reported some evidence in favor of the PIH, researchers that followed Hall’s methodology often failed to find evidence supporting the PIH.\(^2\) Because statistical tests of the PIH always include ancillary assumptions, rejections could be due to misspecification of the ancillary assumptions.\(^3\) In the present paper, we focus on the possible misspecification arising from the assumption that only the mean of future income affects individual consumption paths. If individuals consumption decisions are influenced by uncertainty about future income, then the variance of future income should also affect an individual’s consumption path. We posit that the degree of uncertainty about future income is time-varying and that incorrectly ignoring the time-varying income uncertainty leads to rejection of the PIH. We find that time-varying income uncertainty does play a role in determining an individual’s consumption path.

If the marginal utility of consumption is nonlinear, then individuals consumption decisions do not depend only on the mean of future income.\(^4\) With convex marginal utility individuals accumulate precautionary savings, which are savings against uninsurable income risks. A test of the PIH that allows for income uncer-

---

\(^1\)The modern interpretation of permanent income, due to Hall (1978) and Flavin (1981), is consistent with intertemporal choice models but is less general than the original interpretation of Friedman (1957).

\(^2\)Rejections of the simplest version of the PIH, which predicts a martingale property for consumption, are summarized by the terms excess sensitivity (Flavin (1981)) and excess smoothness (Deaton (1987)).

\(^4\)If the marginal utility of consumption is a linear function of consumption, then an individual’s plan for future consumption depends only on the mean of future income. This is often captured with the phrase certainty equivalence.
tainty is thus also a test of the precautionary saving theory. Recent theoretical work indicates that precautionary saving can provide answers to the consumption puzzles pointed out in the traditional certainty equivalent PIH literature. In an effort to provide empirical support for precautionary saving a number of authors have undertaken cross-section studies, which link household income uncertainty with household savings. While some support for precautionary saving has been found, the results are not conclusive.

We focus on time-series, rather than cross-section, variation in income uncertainty. Our time-series of income uncertainty is constructed from aggregate data because no reliable time-series data exists at the household level. Cochrane (1991) and Pischke (1995) argue that aggregate income uncertainty measures typically underestimate household level earnings uncertainty, which suggests that our measure of aggregate income uncertainty provides a lower bound for the total uninsurable income risk faced by households. In addition, if aggregate income fluctuations affect consumers unequally, then Blanchard and Mankiw (1988) show that aggregate income uncertainty may have a large effect on aggregate consumption.

In Section 2, we derive the optimal consumption path for individuals with convex marginal utility who face time-varying income uncertainty. The optimal consumption path leads to testable regression hypotheses for both consumption and savings. We discuss our measure of time-varying income uncertainty in Section 3. Our measure is novel in that it is constructed directly from a survey of professional forecasters rather than from a parametric model for time-varying conditional variances. Because survey data may be contaminated with measurement error, we do not rely only on ordinary least squares (OLS) estimates. We also construct estimators that are consistent in the presence of measurement error.

\footnote{Zeldes (1989) and Caballero (1990) show that precautionary saving may explain the excess sensitivity and excess smoothness features of consumption. The importance of precautionary saving for government policy is studied in Barsky, Mankiw, and Zeldes (1986), Hubbard and Judd (1987), and Feldstein (1988).}

\footnote{Several studies report evidence that supports precautionary saving: Dardanoni (1991, with U.K grouped data for 1984) finds that consumption is systematically lower for individuals in occupations that have greater income uncertainty; Guiso, Jappelli, and Terlizzese (1991, with Italian survey data) find that consumption is slightly lower for individuals with higher income uncertainty; and Carroll and Samwick (1992, with U.S. grouped data) find that the stock of wealth is higher for individual groups that have greater income uncertainty. Other studies report evidence that does not support precautionary saving: Skinner (1988) finds that saving rates are lower for occupations with higher income uncertainty; and Dynan (1993, with the U.S. Consumer Expenditure Survey) finds little evidence of precautionary saving.}
We find that our results, which we report in Section 4, are substantively similar across estimators, which indicates that measurement error is not driving the results. We find that, while time-varying income uncertainty has little role to play in explaining the instantaneous adjustment of consumption, income uncertainty is important in explaining the level of savings. These findings suggest that savings and (nondurable) consumption do not adjust completely in one period. We investigate the possibility that consumption adjustment is not completed within one period, and find that time-varying income uncertainty has a substantial role to play in explaining the adjustment of consumption over a longer horizon.

2. The Effect of Income Uncertainty on Consumption and Savings

We model an infinitely-lived representative consumer who maximizes the expected present value of lifetime utility. We assume that utility is additively separable through time and a function of consumption alone. Let $C_t$ be the value of consumption in period $t$. We assume that the representative consumer has constant absolute risk aversion (CARA) utility of the following form

$$U(C_t) = -\frac{1}{\theta} e^{-\theta C_t}$$

where $U(\cdot)$ is the representative consumer’s utility function and $\theta > 0$ is the coefficient of absolute risk aversion.

In each period the representative consumer maximizes the expected present value of lifetime utility. To represent the consumer’s problem, we follow much of the extant literature and assume that the real interest rate, $r > 0$, is constant and equal to the rate of time preference. Let $E_t$ be the expectation operator conditional on all information available to the consumer in period $t$. To maximize the expected present discounted value of lifetime utility, the representative consumer solves

$$\max_{\{C_{t+i}\}} E_t \sum_{i=0}^{\infty} (1+r)^{-i} U(C_{t+i})$$

subject to the budget constraint $C_{t+i} = Y_{t+i} + (1+r) A_{t+i-1} - A_{t+i}$, where $Y_t$ is the period-$t$ value of labor income and $A_t$ is the end of period-$t$ value of nonhuman wealth that satisfies $\lim_{i \to \infty} (1+r)^{-i} A_{t+i} = 0$. Because future labor income is the
only source of uncertainty for the consumer, labor income is the random variable that drives consumption.

The time path of consumption \( \{C_t\}_{t=0}^{\infty} \) that solves (2.2) is given by the Euler equation

\[
e^{-\theta C_t} = E_t e^{-\theta C_{t+1}}. \tag{2.3}
\]

To understand the effect of uncertainty about future labor income on current consumption, we wish to express the path of consumption that satisfies (2.3) in terms of the innovations to labor income. To capture time-varying uncertainty about future labor income, we allow labor income innovations to have time-varying conditional second moments.

To begin we assume that labor income follows the unit-root process \( Y_{t+1} = Y_t + W_{t+1} \), where \( W_{t+1} \) has a Gaussian conditional distribution that is centered at 0 with variance \( E_t W^2_{t+1} \). We let \( V_{t+1} = C_{t+1} - E_t C_{t+1} \) be the one-step ahead forecast error, so that \( E_t V^2_{t+1} \) is the conditional variance of the consumption forecast error in period \( t + 1 \). If the conditional distribution of \( V_{t+1} \) is Gaussian with mean zero, then (2.3) implies that

\[
C_{t+1} = C_t + \frac{\theta}{2} E_t V^2_{t+1} + V_{t+1}, \tag{2.4}
\]

where \( E_t V^2_{t+1} \) is the conditional variance of the consumption forecast errors.

To relate the optimal consumption path to the innovations to labor income we must relate \( \{V_{t+i}\}_{i=1}^{\infty} \) to \( \{W_{t+i}\}_{i=1}^{\infty} \). To do so, we follow Caballero (1990) and rewrite the intertemporal budget constraint as

\[
\sum_{i=1}^{\infty} \alpha^i [C_t + \sum_{j=1}^{i} \frac{\theta}{2} E_t V^2_{t+j} + \sum_{j=1}^{i-1} \frac{\theta}{2} (E_t W^2_{t+j+1} - E_t V^2_{t+j+1}) + \sum_{j=1}^{i} V^2_{t+j} - \sum_{j=1}^{i} W^2_{t+j} - E_t Y_{t+i}] = A_t, \tag{2.5}
\]

where \( \alpha = (1 + r)^{-1} \). The algebraic steps that lead to (2.5) are not particularly enlightening and are contained in the appendix. If we divide (2.5) into two components, then the basic prediction of the theory of precautionary savings falls out. The component that holds in period \( t \) is given by the period-\( t \) conditional expectation of (2.5)

\[
C_t = \frac{1 - \alpha}{\alpha} \left( A_t + \sum_{i=1}^{\infty} \alpha^i E_t Y_{t+i} \right) - \frac{1 - \alpha}{\alpha} \sum_{i=1}^{\infty} \alpha^i \left( \sum_{j=1}^{i} \frac{\theta}{2} E_t V^2_{t+j} \right). \tag{2.6}
\]
Because \( \frac{1 - \alpha}{\alpha} (A_t + \sum_{i=1}^{\infty} \alpha^i E_t Y_{t+i}) \) equals permanent income, the second term on the right-hand side of (2.6) captures the amount consumption is reduced in the face of uninsurable labor income uncertainty.\(^7\)

The component of (2.5) that holds in future periods, that is, beyond period \( t \), is obtained by substituting the right-hand side of (2.6) into (2.5)

\[
\sum_{i=1}^{\infty} \alpha^i \left( \sum_{j=1}^{i} V_{t+j} + \sum_{j=1}^{i-1} \frac{\theta}{2} (E_{t+j} V_{t+j+1}^2 - E_t V_{t+j+1}^2) - \sum_{j=1}^{i} W_{t+j} \right) = 0. \tag{2.7}
\]

By collecting the terms that correspond to a given period in (2.7) we have that

\[
\left( V_{t+1} \sum_{i=1}^{\infty} \alpha^i - W_{t+1} \sum_{i=1}^{\infty} \alpha^i \right) +

\left( V_{t+2} \sum_{i=2}^{\infty} \alpha^i - W_{t+2} \sum_{i=2}^{\infty} \alpha^i + \frac{\theta}{2} (E_{t+1} V_{t+2}^2 - E_t V_{t+2}^2) \sum_{i=2}^{\infty} \alpha^i \right) + \ldots = 0. \tag{2.8}
\]

Because the budget constraint must be satisfied in each period, \( V_{t+1} = W_{t+1} \). For periods further into the future, \( V_{t+i} \) equals \( W_{t+i} \) adjusted for future revisions in conditional expectations. For period \( t+2 \), \( V_{t+2} = W_{t+2} - \frac{\theta}{2} (E_{t+1} V_{t+2}^2 - E_t V_{t+2}^2) \).

Because \( V_{t+1} \) equals \( W_{t+1} \), (2.4) becomes

\[
C_{t+1} - C_t = \frac{\theta}{2} E_t W_{t+1}^2 + W_{t+1}. \tag{2.9}
\]

For a representative consumer with precautionary savings, changing labor income uncertainty affects the value of consumption that solves the maximization problem (2.2). The positive effect of labor income uncertainty on the change in consumption is due to the reduction in current consumption reflected in (2.6).

Because disposable income is equal to the sum of consumption and savings, a model of consumption is implicitly a model of savings. In fact, the precautionary savings theory argues that income uncertainty directly affects savings and it is the effect on savings that feeds through to consumption. Let \( Y_t^d \) be disposable

---

\(^7\)Our result is distinct from that of Caballero (1990) in that (2.6) is not a closed form solution as the right-hand side contains \( E_t V_{t+j}^2 \).
income in period $t$ and let $Y^p_t$ be permanent income in period $t$. If we substitute the equalities $Y^p_t = \frac{1-\alpha}{\alpha} (A_t + \sum_{i=1}^{\infty} \alpha^i E_t Y_{t+i})$ and $S_t + C_t = Y^d_t$ into (2.6), then

$$S_t = Y^d_t - Y^p_t + \frac{1-\alpha}{\alpha} \sum_{i=1}^{\infty} \alpha^i \left( \sum_{j=1}^{i} \frac{\theta}{2} E_t V^2_{t+j} \right).$$  

(2.10)

From (2.10) we see that $S_t$ has two components. The first component $Y^d_t - Y^p_t$ captures the standard role of saving in smoothing consumption, where saving anticipates future declines in income. The second component $\frac{1-\alpha}{\alpha} \sum_{i=1}^{\infty} \alpha^i \left( \sum_{j=1}^{i} \frac{\theta}{2} E_t V^2_{t+j} \right)$ captures the amount of saving that is due to the riskiness of expected future labor income. That is, if uncertainty about expected future income increases, then saving increases.

2.1. Regression Specification

Our test of precautionary saving is based on the significance of the conditional variance of labor income shocks in a regression with a function of consumption or saving as the dependent variable. To ensure that our estimators are constructed from stationary random variables, and that our estimates are comparable with those contained in previous studies, we use the consumption growth rate as a dependent variable rather than the first difference of consumption. Similarly, we use savings rates, rather than the level of savings, as a dependent variable.

We begin with specification of the consumption regression. To transform (2.9), we divide both sides by $C_t$ and multiply and divide the right-hand side by $Y^2_t$ and estimate the consumption adjustment regression

$$\Delta \ln C_{t+1} = \beta_0 + \beta_1 \frac{Y^2_t}{C_t} E_t \frac{W^2_{t+1}}{Y^2_t} + \frac{W_{t+1}}{C_t},$$

(2.11)

where $(\beta_0, \beta_1)$ is a vector of parameters. Under rational expectations $E_t \frac{W^2_{t+1}}{C_t} = 0$, so $\frac{W_{t+1}}{C_t}$ is interpretable as the forecast error for the consumption growth rate and $E_t \frac{W^2_{t+1}}{Y^2_t}$ is interpretable as the forecast error variance for the logarithm of labor income.\(^8\) The precautionary saving theory implies that $\beta_1 = \frac{\theta}{2}$ is positive, although the magnitude of $\beta_1$ depends on the degree of risk aversion. The presence

\(^8\)Our results accord with previous results derived (under the assumption that the representative consumer has constant relative risk aversion (CRRA) utility) by Skinner (1988) and Zeldes (1989) who show that precautionary saving affects the optimal consumption path. Although
of the regressor $\frac{Y_t^2}{C_t^2} E_t \frac{W_{t+1}^2}{Y_t^2}$ in (2.11) indicates that under precautionary saving, the conditional expectation of the consumption growth rate is not constant but a function of income uncertainty.

Accounting for precautionary saving may also help explain the empirical finding that the expected income growth rate predicts the consumption growth rate. This finding, often referred to as the excess sensitivity of consumption, may simply arise from the fact that income uncertainty is incorrectly omitted from the regression and that income uncertainty is correlated with expected future income. To test for excess sensitivity of consumption under change income uncertainty, we test the null hypothesis that $\beta_2$ equals zero in the consumption adjustment regression

$$\Delta \ln C_{t+1} = \beta_0 + \beta_1 \frac{Y_t^2}{C_t} E_t \frac{W_{t+1}^2}{Y_t^2} + \beta_2 E_t \Delta \ln Y_{t+1}^d + \frac{W_{t+1}}{C_t},$$

(2.12)

where $E_t \Delta \ln Y_{t+1}^d$ is the expected growth rate of disposable income.\(^9\)

To obtain a specification for the savings regressions, we begin with a savings adjustment regression that is analogous to (2.11). To transform (2.9) we replace $C_t$ with $Y_t^d - S_t$ and divide both sides by $Y_t^d$:

$$\frac{\Delta S_{t+1}}{Y_t^d} = \beta_0 + \beta_1 Y_t^d E_t \frac{W_{t+1}^2}{Y_t^2} + \beta_2 \Delta \ln Y_{t+1}^d + \frac{W_{t+1}}{Y_t^d},$$

(2.13)

where $\beta_1 = -\frac{4}{2}$ and $\beta_2 = 1$. Once again, an increase in the conditional variance of the income growth rate reduces $\Delta S_{t+1}$ because it increases $S_t$ leaving $S_{t+1}$ unchanged.

\(^9\)Campbell and Mankiw (1989, 1990) construct a model in which there are two types of consumers: those who consume current income (due to liquidity constraints); and those who consume permanent income. The extension of their model into our framework implies that $\beta_2$ in (2.12) represents the share of consumers who consume current income. Campbell and Mankiw, who omit the uncertainty term, report point estimates of $\beta_2$ that cluster around .5, indicating that only half of income falls to consumers who follow the PIH. Of course, improperly omitting the uncertainty term biases the estimator of $\beta_2$. In fact, if $\beta_1 > 0$ in (2.12) and the uncertainty term and $\Delta \ln Y_{t+1}^d$ are positively correlated, then omission of the uncertainty term leads to an upward bias in the instrumental variables estimator of $\beta_2$, which understates the adequacy of the PIH to describe consumption.
All of the specifications given above assume that adjustment in consumption and savings occurs completely within a given period as income uncertainty changes over time. As Carroll (1992) conjectures, instantaneous adjustment in consumption may be difficult, so that the level of consumption and savings may adjust incompletely within one period in the face of an increase in the level of income uncertainty. To determine the level of empirical support for incomplete adjustment in consumption and savings, we first estimate a savings level regression. To derive a specification for a savings, rather than a savings adjustment, regression we approximate (2.10). To approximate we replace $Y_t^p$ with $Y_{t+1}^d$ and we replace the third term on the right-hand side of (2.10) with $E_t W_{t+1}^2$. We then divide both sides by $Y_t^d$ and replace $E_t W_{t+1}^2$ with $E_t W_{t+1}^2$:

$$
\frac{S_t}{Y_t^d} = \beta_0 + \beta_1 Y_t^d E_t \frac{W_{t+1}^2}{Y_t^d} + \beta_2 E_t \Delta \ln Y_{t+1}^d - \frac{W_{t+1}^2}{Y_t^d}.
$$

(2.14)

The precautionary saving theory predicts that $\beta_1$ is positive and $\beta_2$ is negative; the latter implication follows because higher expected future income lowers saving, as in standard certainty-equivalence permanent income models (Campbell (1987)).

Strong evidence for precautionary saving from (2.14) but not from (2.12) and (2.13), provides evidence that a change in income uncertainty in period $t$ affects both $S_t (C_t)$ and $S_{t+1} (C_{t+1})$. To capture incomplete adjustment in response to changing income uncertainty we estimate the following consumption and savings adjustment regressions

$$
\ln C_{t+p} - \ln C_t = \beta_0 + \beta_1 \frac{Y_t^2}{C_t} E_t \frac{W_{t+1}^2}{Y_t^2} + U_{t+p},
$$

(2.15)

$$
\ln C_{t+p} - \ln C_t = \beta_0 + \beta_1 \frac{Y_t^2}{C_t} E_t \frac{W_{t+1}^2}{Y_t^2} + \beta_2 E_t (\ln Y_{t+p}^d - \ln Y_t^d) + U_{t+p},
$$

(2.16)

where $p$ is the number of quarters over which the adjustment process takes place. If $p$ is greater than 1, the adjustment process is not completed within one period implying that an increase in income uncertainty in period $t$ lowers consumption in

\[10\] A number of authors have shown that consumption adjustment is incomplete within one period in their models: Constantinides (1990) and Heaton (1990) who include habit formation; Goodfriend (1992) and Pischke (1995) who include information lags; and Bertola and Caballero (1990) who include other adjustment costs.
both period $t$ and period $t+1$, so the sign on the coefficient of income uncertainty in the standard Euler equation is not clear. Clearly, if the adjustment process takes $p$ periods or less, an increase in income uncertainty in period $t$ leaves consumption in period $t+p$ unchanged, so the coefficient on income uncertainty in (2.15) is positive. To estimate the model we set $p$ equal to four to capture adjustment processes that are not instantaneous but are completed within one year.

3. Data

Our data set is novel in that we use a survey measure of income uncertainty. Recall that our regression model requires the conditional variance of the income growth rate as a regressor. Because we observe only one time-series for income, we cannot construct a conditional variance of the income growth rate from the observed time series on income without parametric assumptions. One set of parametric assumptions, which is popular in the empirical finance literature, is to parameterize the conditional variance with a generalized autoregressive (GARCH) model. Yet any parametric model suffers from the weakness that there is little economic motivation for the specific parametric form of the model. The problem is potentially serious as results often differ substantially over different parametric forms. We are able to avoid the problem by using what is in effect a nonparametric measure of conditional variance. That is, rather than trying to infer the conditional variance of income growth rates from past observations of income, we have a direct measure, namely the survey responses of forecasters of income.

Why do the surveyed income forecasts provide information on the conditional variance of income? To understand why, consider the following model

$$\Delta \ln Y_{t+1} = \mu_t + V_{t+1},$$

where $\mu_t$ is the conditional mean given all information available in period $t$ and $V_{t+1}$ is the forecast error. The conditional variance in the income growth rate, where use of the word conditional means conditional on period $t$ information, is the conditional variance of the forecast error. Because each of the forecasters in the panel reports income for the next four quarters, we have forecasts of income growth rates. Because we have a panel of forecasters at each quarter, we can directly calculate the conditional variance of the forecast error as the variance, across forecasters, of the income growth rate at each quarter.
Of course survey measures are not without drawbacks. Our survey was initially gathered by the American Statistical Association, in conjunction with the National Bureau of Economic Research, and begun in 1968. Over time, responsibility for gathering the survey data has shifted to the Federal Reserve Bank of Philadelphia. Each of the institutions could potentially survey different groups. (In fact, the Federal Reserve Bank of Philadelphia has attempted to continue the original survey design used by the ASA/NBER and the survey group is restricted to professional forecasters.) Note that we do not have a panel of forecasters, in which we track a specific group of forecasters over a given time period. Rather, our individual forecasters exit and enter the survey and they occasionally fail to respond. Thus we have different numbers of responses in different quarters and we do not track a consistent group of forecasters. Further, the number of responses differs from period to period. Because we do not sample the exact same group of forecasters in each period, and even if we did because our group of professional forecasters does not cover the entire population, our regressor is measured with error. In the econometric work we describe below, we take care to treat measurement error and calculate estimators of the parameters that are consistent in the presence of measurement error. Details on construction of a measurement-error consistent estimator are contained in the appendix.

To construct our measure of income uncertainty, \( E_t \frac{W_{t+1}^2}{\gamma_t^2} \), we use survey responses for real GDP. Although the model in Section 2 is constructed from labor income, the closest measure to labor income in our survey is real GDP. Each survey response contains forecasts of the level of real GDP four quarters into the future. From the forecast level of GDP we construct the implicit forecast of the growth rate of real GDP.

Our measurements of the other variables, namely consumption, disposable income, and savings are drawn from the U.S. National Income and Product Accounts. For \( C_t \) we use quarterly consumption of nondurables and services, for \( Y_t^d \) we use quarterly disposable personal income, and for \( S_t \) we use quarterly personal savings, where all series are per capita and measured in 1987 dollars.\(^\text{11}\) Because survey data for real GDP is gathered beginning in the third quarter of 1981, our

\(^{11}\)The survey response is a forecast of real GDP rather than per capita real GDP. We constructed the conditional variance of surveys for the growth rate of real GDP and per capita real GDP. Because our conditional variance measures were virtually identical, which reflects the stability of the population growth rate over our sample, we use the conditional variance of the growth rate of real GDP because that is the quantity reported in the survey.

11
sample period begins in the third quarter of 1981 and continues through the fourth quarter of 1994.

Table 1 presents descriptive statistics of the data used in the empirical analysis. In panel a, the first row contains the mean and the second row contains the standard deviation of each variable. Panel b contains the matrix of correlations between the variables. The estimated correlations in panel b support the theory, namely that our income uncertainty measure \( E_t \frac{w^2_{t+1}}{\sigma^2_t} \) is positively correlated with both real per capita consumption growth rates and savings rates and is negatively correlated with the ratio of the change in savings to disposable income.

We present the mean forecast growth rate and the actual growth rate of real GDP in Figure 1. As the figure indicates, the growth rate forecasts are unbiased (the average deviation over the entire sample is -.0436 percent per year with a standard deviation of 2.5773). The correlation between the mean forecast growth rate and the actual growth rate is .51. In Figure 2 we plot the conditional standard deviation of the income growth rate from the survey. As can be seen from the Figure 2, there is a marked change in the conditional variance of the forecasts over time. This might reflect the high variability of inflation in the early 1980’s.

4. Empirical Results

For each regression specification we test the significance of income uncertainty. More precisely, we test the null hypothesis that the PIH without income uncertainty holds against the alternative hypothesis that the PIH with income uncertainty holds. For each specification, the null and alternative hypotheses have precise implications for the coefficient on the uncertainty term; namely \( \beta_1 = 0 \) under the null hypothesis and \( \beta_1 > 0 \) under the alternative hypothesis for the consumption adjustment and savings rate regressions, and \( \beta_1 = 0 \) under the null hypothesis and \( \beta_1 < 0 \) under the alternative hypothesis for the savings adjustment regressions. Because the alternative hypothesis for \( \beta_1 \) is one sided, we construct one-sided significance tests for \( \beta_1 \). Rejection of the null hypothesis is thus support for our model.

Many of the specifications contain an additional regressor that is a function of expected disposable income. The coefficient on this additional regressor, \( \beta_2 \), is assumed to have the same value under both the null and alternative hypotheses for \( \beta_1 \). As a result, it is not a simple matter to construct joint significance tests. We proceed by constructing separate significance tests. Tests of \( \beta_2 \) are general
tests of the adequacy of the PIH with income uncertainty. Because violations of the PIH imply a two-sided rejection region for $\beta_2$, we use two-sided significance tests for $\beta_2$.

4.1. Instantaneous Adjustment

To determine the adequacy of the prediction that consumption adjusts instantaneously to changes in income uncertainty, in Table 2 we report estimates from (2.11) and (2.12). In Table 2 (as in each of the remaining tables) $\hat{\beta}$ denotes the least squares estimator (two-stage least squares for specifications that contain $E_t \Delta \ln Y_{t+1}^d$ and OLS for all other specifications) and $\hat{\beta}^{me}$ denotes the measurement-error consistent estimator.\footnote{To ensure that our results are driven by uncertainty about the income growth rate, rather than by variables such as $Y_{t+1}^d$ or $Y_t^d$, we estimate all regressions with the uncertainty regressor set equal to $E_t \frac{\Delta Y_{t+1}^d}{\Delta Y_t^d}$. The results from these regressions, which are available on request, are essentially the same as the results we report.} In parentheses below $\hat{\beta}$ we report estimated (serial-correlation and heteroskedasticity consistent) standard errors and below $\hat{\beta}^{me}$ we report either the appropriate fractiles from the empirical distribution of $\hat{\beta}^{me}$ for one-sided tests or the standard error from the empirical distribution for two-sided tests. We use the empirical distribution for $\hat{\beta}^{me}$ constructed from bootstrap resampling because the asymptotic covariance matrix is not easily obtained. (Details of the bootstrap algorithm are in the Appendix.) Again, because the alternative hypothesis is one sided, we reject the null hypothesis if the fractile corresponding to the lower 5 percent of the empirical distribution of $\hat{\beta}^{me}$ exceeds 0.

From panel a, which contains estimates for (2.11), we see that both estimates of $\beta_1$ are positive as theory predicts. However, both estimates are also insignificant at the 5 percent significance level. (The estimated value of $\hat{\beta}^{me}$ is not significant because the upper 95 percent range includes zero as indicated by the negative value for the 5 percent fractile.) From panel b, which contains estimates for (2.12), both estimates of $\beta_1$ are again positive. Further, $\hat{\beta}_1$ is significant (recall that the appropriate critical value 1.645) although $\hat{\beta}_1^{me}$ is insignificant at the 5 percent significance level.\footnote{We use two-stage least squares to estimate regressions with income growth rates. The regressors for the first-stage regression are: a constant, the first four lags of both income growth rates and consumption growth rates, and the first lag of the logarithm of $C_t/Y_t$.} Because the PIH implies $\beta_2 = 0$ for the specification in panel b, the statistically insignificant estimates of $\beta_2$ support the PIH.
our consumption adjustment regressions provide some evidence that income uncertainty affects consumption (although measurement error could be driving the effect) and that income uncertainty removes the effect of expected income growth on consumption as indicated by the insignificant estimates of \( \beta_2 \) in panel b.

Next we turn to the savings regressions in Table 3. In panel a we report results on the savings adjustment regression (2.13). Both \( \beta_1 \) and \( \beta_1^{me} \) are negative, as predicted by the precautionary savings theory. While \( \beta_1 \) is insignificant at the 5 percent significance level, \( \beta_1^{me} \) is significantly less than zero, as indicated by the negative 95 percent fractile. Correcting for measurement error results in evidence in support of the precautionary savings theory, as an increase in income uncertainty raises current savings \( S_t \) and lowers \( \Delta S_{t+1}/Y_t^{d} \). Because the PIH implies \( \beta_2 = 1 \) for the specification in panel a, the result that both estimates of \( \beta_2 \) are not significantly different from one supports the PIH.

Further evidence in support of the precautionary saving theory is contained in panel b, where we report results for the savings rate regression (2.14). Both \( \beta_1 \) and \( \beta_1^{me} \) are significantly greater than zero, which implies that increasing income uncertainty increases savings immediately.\(^{14}\) To assess the magnitude of the effect, we use \( \beta_1^{me} \) to infer that a one standard deviation increase in the conditional variance of the income growth rate, given that \( Y_t \) is set to the sample mean value of 13.58 (in thousands of 1987 dollars), leads to an increase in the saving rate of approximately 1.1 percentage points. Note that the estimates of \( \beta_2 \), which is the coefficient on the instrumented income growth rate, are significantly less than zero. The negative estimates are consistent with the savings behavior of forward-looking consumers under the PIH, as noted by Campbell (1987).

4.2. Incomplete Adjustment

The results from the savings rate regression indicate that income uncertainty has an effect on current savings, but the effect is not easily detected in savings and consumption adjustment regressions. The reason may be that the adjustment process takes more than one period. If this is the case then a change in income uncertainty today affects consumption and savings today and tomorrow and the measured effect on the difference is reduced. To measure the impact of incomplete adjustment within one period, in Table 4 we report empirical results for (2.15)

\(^{14}\)Carroll (1992) obtains similar results with an unemployment expectations measure as the uncertainty regressor.
and (2.16). In panel a, both $\hat{\beta}_l$ and $\hat{\beta}_l^{me}$ are significantly greater than zero, which provides evidence that income uncertainty affects consumption but that the adjustment requires more than one period.

In panel b we report estimates from (2.16), which includes the expected income growth rate as a regressor. For both the 2SLS and the consistent estimator the same result emerges. Income uncertainty has a significantly positive effect on the change in consumption. Further, the estimated coefficient on the expected income growth rate is insignificant.\footnote{Because the shock to consumption is the shock to income the income growth rate regressor $(\ln Y_{t+p} - \ln Y_t)$ is correlated with the regression error. To remove the correlation we use two-stage least squares, where the instruments used in the first-stage regression are: $(\ln Y_t - \ln Y_{t-p})$; $(\ln Y_{t-p} - \ln Y_{t-2p})$; $(\ln C_t - \ln C_{t-p})$; $(\ln C_{t-p} - \ln Y_{t-2p})$; and $\ln(C_t/Y_t)$.

5. Concluding Remarks

We derive and estimate a simple framework in which consumers optimally revise their intertemporal consumption plan not only in response to changes in the level of permanent income but also to changes in their uncertainty about future income. We find that our measure of income uncertainty changes significantly over time, indicating that the popular assumption of constant income uncertainty over time is misleading. Further, the precautionary savings response to changing income uncertainty is a significant source of observed changes to both consumption and saving, and the higher the uncertainty level, the more precautionary savings consumers accumulate. However, the adjustment does not seem to occur instantaneously, possibly due to information lags or adjustment costs. The estimates from the incomplete adjustment model indicate that the excess sensitivity of consumption to current income may be partially explained by the role of time-varying income uncertainty operating through precautionary savings.

The overall evidence indicates that there exist forward-looking consumers who adjust precautionary savings in response to changing income uncertainty. Although our research focuses on consumption of nondurable goods and services, our results also have implications for consumption of durable goods. Because
durable consumption is believed to be quite volatile over the business cycle and sensitive to consumer sentiment, future models of the optimal consumption of durable goods should include time-varying income uncertainty. The consumption response to changes in uncertainty about future income, which is the optimal precautionary savings response, is a potentially important and previously overlooked component of adjustment in both consumption and savings.
**APPENDIX**

*Derivation of the budget constraint*

To derive (2.5), we add and subtract the conditional expectation of $Y_{t+i}$ and substitute recursively for $A_{t+i}$ in the period-$t$ budget constraint, which yields

$$
\sum_{i=1}^{\infty} \alpha^i C_{t+i} - \sum_{i=1}^{\infty} \alpha^i (Y_{t+i} - E_t Y_{t+i}) - \sum_{i=1}^{\infty} \alpha^i E_t Y_{t+i} = A_t.
$$

(5.1)

Because $\{Y_t\}$ is a unit-root process, $Y_{t+i} - E_t Y_{t+i} = \sum_{j=1}^{i} W_{t+j}$. Because (2.4) implies that $C_{t+i} = C_{t+i-1} + \frac{\theta}{2} E_{t+i-1} V_{t+i}^2 + V_{t+i}$ for any value of $i$:

$$
C_{t+i} = C_t + \sum_{j=1}^{i} \frac{\theta}{2} E_t V_{t+j}^2 + \sum_{j=1}^{i-1} \frac{\theta}{2} (E_{t+j} V_{t+j+1}^2 - E_t V_{t+j+1}^2) + \sum_{j=1}^{i} V_{t+j}.
$$

(5.2)

The constraint (2.5) then follows by substituting into (5.1): (i) the right-hand side of (5.2) for $C_{t+i}$; and (ii) $\sum_{j=1}^{i} W_{t+j}$ for $Y_{t+i} - E_t Y_{t+i}$.

*Measurement-error consistent estimator*

As is well known, if a regressor is measured with error OLS estimators are inconsistent. The measurement error problem is essentially an identification problem. To restore identification, and hence consistency, we turn to sufficient assumptions to separately identify the coefficients of the variables that are measured with error. To simplify notation let $H_t = Y_t^2 / C_t E_t W_{t+1}^2$ and let $G_t$ generically denote the dependent variable. We do not observe $H_t$ because it contains $E_t W_{t+1}^2$, rather we observe a contaminated version $H_t' = H_t + M_t$ where $M_t$ denotes measurement error. If we assume that mismeasurement of the conditional variance is not systematic, so that $E M_t = 0$ and $E M_t^3 = 0$, and that the regression error is symmetrically distributed, then we are able to derive a consistent and asymptotically normal method of moments estimator. (See Pal (1980) for more details.) Our measurement-error consistent estimator of $\beta_1$ is $\hat{\beta}_1^{me} = \hat{\beta}_1^{me}_{one}$, where $m_{1} = T^{-1} \sum_t (H_t - \bar{H})^2 (G_t - \bar{G})$, $m_{30} = T^{-1} \sum_t (H_t - \bar{H})^3$.

To construct standard errors for $\hat{\beta}_1^{me}$, we use a bootstrap method. For the bootstrap simulations we first estimate the regression model to obtain $\hat{\beta}^{me}$ and the residuals $\{\hat{U}_t\}_{t=1}^n$. We then estimate an AR(1) process for the residuals, $\hat{U}_t = \rho \hat{U}_{t-1} + V_t$, to obtain $\hat{\rho}$ and a second set of residuals $\{\hat{V}_t\}_{t=1}^n$. (We use the AR(1) specification throughout, because there is little evidence of serial correlation in
\{\hat{V}_t\}_{t=1}^n. \) We sample with replacement from the white-noise sequence \{\hat{V}_i\}_{i=1}^n to obtain a bootstrap sample \{\hat{V}_i^*\}_{i=1}^n. For each bootstrap sample, we use \hat{\rho} to construct \{\hat{U}_i^*\}_{i=1}^n and then use \{(\hat{\beta}_{mec}^*, \{H_t\}_{t=1}^n, \{\hat{U}_t^*\}_{t=1}^n)\) to construct \{G_t^*\}_{t=1}^n. For each bootstrap sample \{G_t^*, H_t\}_{t=1}^n we obtain a bootstrap value of the estimator \hat{\beta}_{mec}^*). We repeat the procedure 1000 times to create a bootstrap distribution \(F^*(\hat{\beta}_{mec}^*)\). Because theory implies that \(\beta_1\) is positive, we calculate the 5 percent fractile to form a one-side significance test.

Growth rates for $C_t$ and $Y_t$ are measured in percent per year.
Table 2

a. Consumption Adjustment Regression

\[
\Delta \ln C_{t+1} = \beta_0 + \beta_1 \frac{\gamma^2}{\alpha^2} E_t \frac{W^2_{t+1}}{Y_t^2} + U_{t+1}
\]

\[\hat{\beta}_1 \quad \hat{\beta}_1^{me} \]
\[.0042 \quad .0029 \]
\[(.0032) \quad F_{05} = -.0013 \]

b. The Permanent Income Hypothesis under Changing Income Uncertainty

\[
\Delta \ln C_{t+1} = \beta_0 + \beta_1 \frac{\gamma^2}{\alpha^2} E_t \frac{W^2_{t+1}}{Y_t^2} + \beta_2 E_t \Delta \ln Y_{t+1}^d + U_{t+1}
\]

\[\hat{\beta}_1 \quad \hat{\beta}_1^{me} \quad \hat{\beta}_2 \quad \hat{\beta}_2^{me} \]
\[.0049^* \quad .0029 \quad .2133 \quad .1832 \]
\[(.0029) \quad F_{05} = -.0014 \quad (.1164) \quad (.1325) \]

An * indicates rejection of the null hypothesis at the 5 percent significance level. Because the alternative hypothesis is \(\beta_1 > 0\), we reject the null hypothesis that \(\beta_1 = 0\) at the 5 percent significance level if the fractile corresponding to the lower 5 percent of the empirical distribution of \(\hat{\beta}_1^{me}\) exceeds zero.
a. Saving Adjustment Regression

\[ \frac{\Delta s_{t+1}}{y^t} = \beta_0 + \beta_1 Y_t^d E_t \frac{\Delta w_{t+1}^d}{y^t} + \beta_2 \Delta \ln Y_{t+1}^d + U_{t+1} \]

\[ \hat{\beta}_1 \quad \hat{\beta}_{1me} \quad \hat{\beta}_2 \quad \hat{\beta}_{2me} \]

\[-.0086 \quad -.0136^* \quad .6962 \quad .7369 \]

\( F_{.95} = -.0076 \quad (.3017) \quad (.2384) \)

b. Savings Rate Regression

\[ \frac{s_t}{y^t} = \beta_0 + \beta_1 Y_t^d E_t \frac{\Delta w_{t+1}^d}{y^t} + \beta_2 \Delta \ln Y_{t+1}^d + U_{t+1} \]

\[ \hat{\beta}_1 \quad \hat{\beta}_{1me} \quad \hat{\beta}_2 \quad \hat{\beta}_{2me} \]

\[ .0177^* \quad .0170^* \quad -.4141 \quad -.4980 \]

\( F_{.95} = .0144 \quad (.1188) \quad (.1061) \)

An * indicates rejection of the null hypothesis at the 5 percent significance level. Because the alternative hypothesis is \( \beta_1 < 0 \) for the specification in panel a, we reject the null hypothesis that \( \beta_1 = 0 \) at the 5 percent significance level if the fractile corresponding to the upper 95 percent of the empirical distribution of \( \hat{\beta}_{1me} \) is less than zero.
Table 4

a. Consumption Adjustment Regression

\[ \ln C_{t+4} - \ln C_t = \beta_0 + \beta_1 \frac{Y_t^2}{C_t^2} E_t \frac{W_{t+1}^2}{Y_t^2} + U_{t+4} \]

\[ \hat{\beta}_1 \quad \hat{\beta}_{1me} \]

.0056* .0041*

(.0022) \quad F_{0.05} = .0003

b. Excess-Sensitivity of Consumption to Current Income

\[ \ln C_{t+4} - \ln C_t = \beta_0 + \beta_1 \frac{Y_t^2}{C_t^2} E_t \frac{W_{t+1}^2}{Y_t^2} + \beta_2 E_t (\ln Y_{t+4}^d - \ln Y_t^d) + U_{t+4} \]

\[ \hat{\beta}_1 \quad \hat{\beta}_{1me} \quad \hat{\beta}_2 \quad \hat{\beta}_{2me} \]

.0056* .0041* .2268 .1983

(.0019) \quad F_{0.05} = .0002 \quad (.1365) \quad (.1773)

An * indicates rejection of the null hypothesis at the 5 percent significance level.
